Abstract - Cloud computing is a market-oriented computing paradigm with virtually unlimited scalable high performance computing resources. The high level middleware services for cloud computing and cloud workflow systems are research frontier for both cloud computing and workflow technologies. In this paper, the extension of Cloud management infrastructure with Service Level Agreement (SLA) aware application and motivating scenario for the development of the scheduling heuristic after which, the detail design and implementation of the heuristic are mentioned.

Keywords : qos, SaaS, SLA, lom2his, cloudsim , vm, iaas, PaaS.

I. Introduction

Cloud Computing is a computing paradigm [2, 6] that refers to variety of services available on internet which delivers computing functionality on the service provider’s infrastructure. Cloud is a pool of virtualized computer resources and may be hosted on grid or utility computing environments [1, 7]. Its potential feature which includes the ability to scale, to meet changing users demand, separation of infrastructure maintenance duties from users, location of infrastructure areas with electricity, sharing of peak load capacity and so on. In this modern technical ear, the recent popularity of cloud computing on the scenario of data and computation and investigation of intensive scientific workflow applications like, climate modeling, earthquake modeling, weather forecasting, disaster recovery simulation, Astrophysics and high energy physics [5, 8, 9]. These scientific processes can be modeled or redesigned as scientific cloud workflow specifications at build-time modeling stage [5]. These specifications contain number of data computation activities and their non-functional requirements such as Quos constraints on time and cost basis [10]. At runtime execution stage, with the support of cloud workflow execution functionalities such as workflow scheduling [11], load balancing [3] and temporal verification [4], cloud workflow instances are executed by employing the supercomputing and data sharing ability computing infrastructures with satisfactory Quos.

Scientific applications are time constrained which required to be completed by satisfying a set of temporal constraints and global temporal constraints. The task execution time is the basic measurements for system performance, which need to be monitored and controlled by specific system management mechanisms. To ensure satisfactory temporal correctness and on time completion of workflow application is a critical issue for enhancing the overall performance. Cloud customers are interested in cost effective deployment of single applications in clouds, which is common in the Software as a Service (SaaS) delivery model. Commercial cloud providers such as sales force [24] are offering the provision for single applications based on agreed SLA terms. Commercial providers use custom techniques, which are not open to the general public. To foster competitive cloud market and reduce cost, the need for open solutions is must.

In Figure – 1, a motivating scenario for the development of scheduling and deployment heuristic is represented. The use case scenario shows a Cloud provider and pools of customers who wish to deploy

\begin{figure}[h]
  \centering
  \includegraphics[width=\textwidth]{motivation_scenario.png}
  \caption{Scheduling Motivation Scenario}
  \label{fig:motivation}
\end{figure}

...
their applications on the Cloud resources based on the pre agreed SLA objectives. The application of how to deploy the available virtual machines in the Cloud to ensure their performance and enforce the agreed SLA objectives including the challenge to manage resources to achieve high utilizations and maximum deployments by grid scientific computing [17]. A novel scheduling heuristic considering multiple SLA parameter objectives, such as amount of required CPU, network bandwidth, and storage in deploying applications on Clouds is mentioned. The heuristic includes a load-balancing mechanism for efficient distribution of the applications’ execution on the Cloud resources. We also present a flexible on-demand resource allocation strategy included in the heuristic for automatically starting new virtual machines (VM) when a non-appropriate VM is available for application deployment. The concept and detailed design of the heuristic including its implementation in the Clouds simulation tool [15, 16]. The scheduling strategy proposed in this section is integrated into the LoM2HiS framework as shown in Figure - 2.

II. RESOURCE PROVISIONING

The idea of Cloud computing is to provide resources as a service in a flexible and scalable manner [14]. There are three well known types of resource provisioning [21, 23] in Cloud:

i. Infrastructure as a Service (IaaS) that offers bare hardwires such as the physical machines, storage devices, and network infrastructures as a service. Amazon EC2 [12] is an example of IaaS offering;

ii. Platform as a Service (PaaS), which delivers platform for application development and deployment as a service [20]. It typically utilizes virtualized resources in form of virtual machines that are capable of provisioning resources to applications. A typical example of PaaS service is the Google App Engine [20];

iii. Software as a Service (SaaS) offering resources for the provisioning of single Applications in a Cloud environment. Vendors of SaaS include salesforce.com [24].

The Cloud provisioning and deployment model presented in Figure - 3 shows a scenario combining the three different types of resource provisioning to host service requested from customers. The customers place their service deployment requests to the service portal, which passes the requests to the request processing component to validate the requests. If the request is validated, it is then forwarded to the scheduler. The scheduler selects the appropriate VMs through the provisioning engine in PaaS layer for deploying the requested service and the load balancer balances the service provisioning among the running VMs. The provision engine manages the VMs on the virtualization layer and the virtualization layer interacts with the physical resources via the provision engine in IaaS layer. The low-level resource metrics of the physical resources at the IaaS layer are monitored by the LoM2HiS framework [19]. The service status and the SLA information are communicated back to the service portal [22]. Although, the scenario described above is a possible way of combining the three types of resource provisioning, there exist other scenarios like provisioning of virtual machines alone and provisioning of physical resources alone, which are possibilities of provisioning at the single layers alone.

However, our approach aims to provide an integrated resource provisioning strategy. The proposed scheduling heuristics considers the three layers. Efficient resource provisioning and application deployments at these layers are not trivial considering their different constraints and requirements. At the IaaS layer the physical resources must be managed to optimize utilizations. At the PaaS layer, the VMs have to be deployed and maintained on the physical host considering the agreed SLAs with the customer.

Figure 2 : LoM2HiS with Scheduling Strategy

Figure 3 : Cloud Provisioning and Deployment Model
III. Scheduling and Load Balancing Mechanisms

The proposed scheduling heuristic [18] aims at deploying applications on virtual machines based on the agreed SLA objectives. Moreover, the integrated load-balancer in the heuristic ensures high and efficient resource utilization; consequently saving the provider the cost of maintaining unused resources. In this work, we assume that the SLA terms between the customer and the Cloud provider are already established. Thus, the processes of SLA specification, negotiation, and establishment are out of scope for this work, but there is ongoing research work where the Vie SLAF framework [13] is used to address the issues.

Algorithm - 1:
(Scheduling Heuristic)
1. Input: User Service Request
2. Get Global Resources and Available Vm List;
3. // find appropriate VM List
4. If AP(R, AR)! =; then
5. //call the load balancing algorithm
6. deployable VM = load-balance (AP(R, AR))
7. deploy service on deployable Vm;
8. deployed = true;
9. else
10. If global Resource Able to Host Extra VM then
11. Start new VM Instance;
12. Add VM to Available VM List;
13. Deploy service on new Vm;
14. Deployed = true;
15. Else
16. Queue Service Request Until
17. Queue Time > Waiting Time
18. Deployed = False;
19. End if
20. End if
21. If Deployed then
22. Return Successful;
23. Terminate;
24. Else
25. Return Failure;
26. Terminate;
27. End if
28. If Deployed then
29. Return Successful;
30. Terminate;
31. Else
32. Return Failure;
33. Terminate;
34. End if

By the pseudo code presented in Algorithm - 1, the scheduler receives as input the customers’ service requests (R) that are composed of the SLA objectives (S) and the application data (A) to be provisioned (line 1 in Algorithm - 1). The request can be expressed as R = (S, A). Each SLA agreement has a unique identifier id and a collection of SLA Objectives (SLOs). The SLOs can be defined as predicates of the form:

\[ SLO_{id}(x_i, \text{comp}, \pi_i) \text{ with } \text{comp} \in \{<,\leq,>,\geq,=\} \]  

(1)

Where \( x_i \in \{\text{Bandwidth, Memory, Storage, Availability}\} \) represents sample SLA parameters, \( \text{comp} \) the appropriate comparison operator, and \( \pi_i \) the values of the objectives.

The basis for finding the virtual machine with the appropriate resources for deploying the application, gathers the output of the scheduler and the confirmation about successful deployment or error message in case of failure. In first step, it extracts the SLA objectives information about the total available resources (AR) and the number of running virtual machines in the data center (line 2). The SLA objectives are used to find a list of VMs with the appropriate resources (AP) capable of provisioning the requested service (R). This operation can be expressed as:

\[ AP(R, AR) = \{VM : VM \in AR, \text{capable} (VM, R)\} \]  

(2)

Where capable (VM, R) is a predicate that returns true if the virtual machine is capable of provisioning the particular request or false otherwise (lines 3-4). Once the list of VMs is found, the load-balancer decides on which particular VM to deploy the application in order to balance the load in the data center (lines 5-8).

In case no VM, the appropriate resources running in the data center, the scheduler checks if the global resources consisting of physical machines can host new VMs (lines 9-10). If that is the case, it automatically starts new VMs with predefined resource capacities to provision service requests (lines 11-14). When the global resources cannot host extra VMs, the scheduler queues the provisioning of service requests until a VM with appropriate resources is available (lines 15-16). If after a certain period of time, the service requests cannot be scheduled and deployed, the scheduler returns a scheduling failure to the Cloud admin, otherwise it returns success (lines 17-27). The load-balancer shown in Algorithm - 2 is not an extension of Next-Fit algorithm and has two core differences like:

i. It does not fill a box to the full before starting to fill another one and

ii. It goes back to the half filled boxes to add new items.

The similarity lays in each iteration, does not put items in the last filled box unless there is no other appropriate box among all the boxes. In Algorithm - 2, the load balancer receives as input the appropriate VM list (line 1 in Algorithm - 2). It first gets the number of available running VMs in the data center in order to
The scheduling heuristic without the load-balancer has a worst-case complexity of $O(m + n)$. This complexity is defined by the processes of finding out the resource capacities of the $m$ physical machines and $n$ available virtual machines in the data center. Other operations of the heuristic have constant complexity ($O(1)$) except the process of checking the available resources on the physical machines in order to start new VMs, which has a worst-case complexity of $O(m)$.

The total worst-case complexity of the proposed heuristic is a result of the sum of the scheduling heuristic complexity and the load-balancer complexity expressed at run time is:

$$0(m + n) + 0(n^2) = 0(n^2 + m) \quad (3)$$

**IV. Implementation**

The proposed scheduling heuristic is implemented as a new scheduling policy in the Clouds simulation tool for the purpose of evaluation offering with unique features are:

i. Support for modeling and simulation of large scale Cloud computing environments including data centers, on a single computing machine

ii. A self-contained platform for modeling Clouds, service brokers, resource provisioning and application allocation policies

iii. Capability of simulating network connections among simulated components

iv. Support for simulation of federation Cloud environment able to network resources from both private and public providers.

v. Availability of virtualization engine that aids in creation and management of multiple, independent, and co-hosted virtualized services on a data center’s physical machine

vi. Ability to switch between spaces shared and time-shared allocation of CPU cores to virtualized resources.

Clouds components shown in the custom extensions layer in Figure – 4, has infrastructure level services as modeled by the core layer representing the original Clouds data center, with homogeneous or heterogeneous configuration of their hardware. Each data center instantiates a resource provisioning component that implements a set of policies that allocates resources to computing host and virtual machines. The two groups of Java classes in clouds are:

i) The control policy classes

ii) The simulation specific classes

The control policy classes include the implementations of a new data center broker for interfacing with the data center and our proposed scheduling heuristic. The data center broker is responsible for mediating negotiations between customers and Cloud providers in respect of allocating appropriate resources to customer services to meet their application’s Quos needs and to manage the provider resources in the Clouds.

The extended data center broker includes the capability of running dynamic simulations by removing the burden of statically configuring the whole simulation scenario before starting. With this feature one can...
generate and send in new events (service requests) during the simulation runtime.

The proposed scheduling heuristic provides policies used by the data center broker for allocating resources to applications. The implementations of the heuristic and that of the load balancer are realized with Java methods in a class named SLA Aware Scheduler as shown in Figure - 4. This class is used by the Data center Broker class to schedule, deploy applications, and manage the data center resources.

The simulation specific classes are used in realizing simulation scenarios. This group includes two Java classes named Data center Model and Service Request as shown in Figure - 4. Data center Model class presents methods for flexible instantiation of different data center scenarios for scalable simulations. The Service Request class represents a customer service request. It encapsulates information about the SLA parameter objectives agreed between the customer and the provider and the application data to be provisioned in the Cloud.

The simulation specific classes are used in realizing simulation scenarios. This group includes two Java classes named Data center Model and Service Request as shown in Figure - 4. Data center Model class presents methods for flexible instantiation of different data center scenarios for scalable simulations. The Service Request class represents a customer service request. It encapsulates information about the SLA parameter objectives agreed between the customer and the provider and the application data to be provisioned in the Cloud.

V. Evaluation

The evaluation of the scheduling heuristic demonstrates the resource utilization by the scheduler. It further shows the higher application performance obtainable while compared to an arbitrary task scheduler. The evaluations presented here are realized using the Clouds simulation tool [16].

Here, we begin with the experimental setup and configuration descriptions and basic experimental configurations. The experimental test bed is setup as described in Figure - 5. It demonstrates the processes of placing service request by customers and how our proposed scheduler deploys the service on appropriate Cloud resources.

The Cloud resources comprise physical and virtual machines. Table - 1 shows the resource capacities of the physical machines and the configuration parameters of the virtual machines. Based on the capacities of the physical machine resources and the sizes of the virtual machines, we can start several virtual machines on one physical host in the Clouds simulation engine. To achieve a reasonable application deployment scenario, we use two types of applications each with its own SLA terms to realize heterogeneous workloads. The first workload is extracted from a Web Application (WA) for an online shop and the second workload is a trace of High Performance Computing (HPC) application represented by an image rendering applications such as POV-Ray.

**a) Deployment Efficiency and Resource Utilization**

The evaluation of the efficiency of the proposed scheduler for deploying customer service requests and utilizing the available Cloud resources. The test essence of the on-demand resource provisioning feature, simulate a large data center made up of 60 physical machines and 370 virtual machines. The capabilities of the scheduler are evaluated into two groups:

i) Fixed resource

ii) On-demand resource

In the fixed resource group the on-demand resource provisioning feature is deactivated while in the on-demand resource group, it is activated. The essence of these two groups is to demonstrate the advantages of the on-demand resource provisioning feature. Each group runs three scenarios:

i. The first scenario handles the deployment of only web applications’ service requests.

ii. The second scenario deals only with HPC applications.

iii. The third scenario deals with a mixture of web and HPC applications.

The three scenarios are intended to cover real world deployment situations in the sense that they handle applications from different categories, which exhibit different behaviors in terms of resource consumption. In the scenarios, the service requests are randomly generated and sent to the scheduler for scheduling and deployment. Next, we describe the achieved results in two groups.

i. Fixed resource group

The scheduler schedules and deploys the applications on the available running VM in the data center without the flexibility of starting new VMs when required. The results achieved by the three scenarios of this group are presented in Figure - 6.

In Figure - 6, scenario 1 presents the results of the first evaluation scenario, which handles only web applications. The first bar shows the total resource utilization level achieved among the running VMs in the data center. The resource utilization is measured by checking the number of service applications. The scheduler achieved 100% resource utilization meaning that the resources on each VM were adequately utilized. The second bar shows the total deployment efficiency achieved, which is in this scenario 49.67%. The low deployment efficiency is caused by lack of available resources. The results of the third evaluation scenario are presented as Scenario 3 in Figure - 6. This scenario deals with a mixture of web and HPC applications’ service requests. The scheduler achieved about 94.05% resource utilization in this scenario as shown by the first bar. The inability to achieve 100% resource utilization is caused by the heterogeneous nature of the workload whereby some...
HPC applications cause some resource fragmentation leaving some resource fragments that are not usable by the scheduler. The second bar represents the deployment efficiency of this scenario, which is 61.73%. This is significantly better than the deployment efficiency achieved in the second scenario. This increase in deployment efficiency is attributed by the heterogeneous workload whereby the number of HPC applications’ requests is smaller than in the second scenario.

ii. On-demand resource group

In this group, it is possible for the scheduler to flexibly start new VMs when necessary as far as there are available resources on the physical machines. This feature allows for higher service request deployment and better usage of the resources at the data center. The results obtained by the three evaluation scenarios of this group are depicted in Figure - 7. The first bar shows that the scheduler achieved 100% utilization in this case. The observation in this scenario as compared to the first scenario of the fixed group is the 100% deployment efficiency achieved, which is shown by the second bar. The scheduler made advantage of the flexible on-demand resource provisioning feature to start extra four virtual machines to fully deploy the whole service requests.

The second evaluation scenario results are presented as Scenario 2 in Figure - 7. This scenario deals with only HPC applications. The scheduler achieved 100% resource utilization in scheduling and deploying the HPC applications as depicted by the first bar. That means the available resources are fully utilized. Although the resources were fully utilized, the scheduler could only achieve 80% deployment efficiency. This is better result than 49.67% achieved by the equivalent scenario in the fixed group. The scheduler created extra 229 VMs for the applications deployments thereby reaching the limits of the physical machines and could not achieve 100% deployment efficiency due to ultimate lack of resources in the data center. This problem could be addressed with Cloud federation paradigm. Scenario 3 in Figure - 7 depicts the results of the third evaluation scenario dealing with a mixture of web and HPC applications. The scheduler achieved 98% resource utilization due to resource fragmentations caused by the heterogeneous workload and resource over provisioning.

The last two VMs started on-demand were under-utilized. 100% deployment efficiency was achieved in this scenario by starting 215 VMs on-demand. Comparing the results achieved by the former group scenarios (Figure - 6) against those of the later group (Figure - 7), it can be clearly seen that the later group obtained much better resource utilization rates and deployment efficiencies. This demonstrates the effectiveness and relevance of our proposed scheduling approach in a Cloud environment.

b) Application Performance Comparison

The performance of applications being provisioned in the Cloud simulation test bed but application performance is evaluated in two aspects using the scenarios of the previous section:

i) Response time for the web applications

ii) Completion time for the HPC applications

The result achieved is compared by the proposed scheduler with that achieved by an arbitrary task scheduler. Table 3 presents the applications performance results. The results show the average response time and completion time of the applications while deployed by the two schedulers. It can be clearly seen that our proposed scheduler is two times better than the task scheduler. The good performance of our scheduler is attributed to the fact that it considers multiple performance objectives before deciding on which resource to deploy an application thereby finding the optimal resource combination for the application best performance, whereas the task scheduler considers mainly single objectives in its deployment, which cannot provide the optimal resources for the application best performance. Note that in Table 3 the on-demand resource provisioning feature applies only to our proposed scheduler.
VI. Conclusion

Scheduling and deployment strategies are means of achieving resource provisioning in Cloud environments. A further contribution of this thesis is the development of a novel scheduling heuristic considering multiple SLA objectives in deploying applications in Cloud environments. The heuristic includes load-balancing mechanism for efficient distribution of the applications' execution among the Cloud resources. A flexible on-demand resource usage feature included in the heuristic for automatically starting new VMs when non-appropriate VM is available for the application deployments is presented. The design of the heuristic and its implementations with proposed scheduling heuristic using the Clouds simulation tool is discussed.

In order to manage the deployment of multiple applications on a single virtual machine, a proposed application monitoring architecture (CASViD), which monitors and detects SLA violations at the application layer in Cloud environments. The evaluated architecture on a real Cloud test bed using three types of image rendering application workloads with heterogeneous behaviors necessary to investigate different application provisioning scenarios and to automatically determine the optimal measurement intervals to monitor the application provisioning. By experiments, the proposed architecture is efficient in monitoring and detecting individual application SLA violation situations. Further one can automatically find the optimal measurement intervals by sampling different ones and checking their net utility values. With the realization of CASViD, the capabilities of monitoring and detecting SLA violations of single customer applications being provisioned in a shared host, in addition to the previous resource monitoring techniques, a holistic monitoring model capable of monitoring at different layers in Clouds is provided.
